Component middleware is popular for enterprise distributed systems because it provides effective reuse of the core intellectual property (i.e., the “business logic”). Component-based enterprise distributed real-time and embedded (DRE) systems, however, incur new system integration problems associated with component configuration and deployment. New research is therefore needed to minimize the gap between the development and deployment/configuration of components, such that deployment and configuration strategies can be evaluated well before system integration. This paper uses an industrial case study from the domain of shipboard computing to show how system execution modeling tools can provide software and system engineers with quantitative estimates of system bottlenecks and performance characteristics to help evaluate quality of service of component-based enterprise DRE systems and reduce time/effort in the integration phase. The results from our case study experiments show the benefits of system execution modeling tools and pinpoint where more work is needed.

1. Introduction

Integration challenges of component-based enterprise DRE systems. Enterprise DRE systems in many domains are increasingly developed using applications composed of distributed components running on feature-rich middleware frameworks. The distributed components are designed to provide reusable services to a range of application domains, which are then composed into domain-specific assemblies for application (re)use. Examples of component middleware platforms include Microsoft .NET, Enterprise Java Beans and the CORBA Component Model (CCM).

The transition to component middleware is occurring in enterprise business systems to address problems of inflexibility and reinvention of core capabilities associated with prior monolithic, functionally-designed, and “stove-piped” legacy applications. Legacy applications were developed with the precise capabilities required for a specific set of requirements and operating conditions. Component-based systems, however, are designed to have a range of capabilities that enable their reuse in other contexts. Moreover, these systems are developed in layers, e.g., layer(s) of infrastructure middleware services (such as naming and discovery, event and notification, security and fault tolerance) and layer(s) of application components that use these services in different compositions.

Certain types of component middleware, such as Real-time CCM [14], are also being applied to the domain of enterprise distributed real-time and embedded (DRE) systems, such as shipboard computing environments and supervisory control and data acquisition systems, to provide users with quality of service (QoS) support to process the right data in the right place at the right time over a grid of computers. Some QoS properties required by enterprise DRE systems include the low latency and jitter as expected in conventional real-time and embedded systems, and high throughput, scalability, and reliability as expected in conventional enterprise distributed systems. Achieving this combination of QoS capabilities in enterprise DRE systems developed using component middleware is hard.

Component middleware can also complicate software lifecycle processes by shifting responsibility from software development engineers to software configuration/deployment engineers and systems engineers. Software development engineers traditionally created entire applications in-house using top-down design methods that could be evaluated throughout the lifecycle. In contrast, software configuration and deployment engineers and system engineers today assemble enterprise DRE systems by customizing and composing reusable components, whose combined properties are usually evaluated only during the integration phase. Unfortunately, problems uncovered during integration are much more costly to fix than if they were discovered earlier in the lifecycle. A key research challenge is thus exposing these types of issues (which often have dependencies on components that are not available until late in development) earlier in the lifecycle, e.g., prior to the system integration phase.

Component-based enterprise DRE systems use design-and run-time configuration steps to customize the behavior of reusable components to meet QoS requirements in the context where they execute. Finding the right configurations for components to meet QoS requirements is hard. For example, tuning the concurrency configuration of a DRE shipboard computing system to support both real-time and fault-tolerant QoS involves trade-offs that challenge even the most experienced engineers. Moreover, application functionality is distributed over many components in a DRE system and developers must interconnect and integrate their components correctly and
efficiently. This process can be tedious and error-prone using conventional handcrafted configuration processes.

The components assembled into an application must also be deployed on the appropriate nodes in an enterprise DRE system. This deployment process is hard since host and network characteristics can vary statically (e.g., due to different hardware/software platforms used in a product-line architecture) and dynamically (e.g., due to damage/faults, change in computing objectives, or differences in the real vs. expected behavior of applications during actual operation). Evaluating the operational characteristics of system deployments is therefore tedious and error-prone when deployments are performed manually.

Another complexity of evaluating deployments of component-based enterprise DRE systems stems from applications sharing components with differing QoS requirements, such as a system resource manager responsible for processing requests from high-priority tactical applications and low-priority desktop applications. It is hard to assure that a stand-alone application can meet stringent QoS requirements using dedicated resources. It is harder to assure these requirements with components sharing resources with other applications in enterprise DRE systems.

**Solution approach → System execution modeling tools.** Despite the flexibility offered by component middleware, there are often surprisingly few configuration and deployment designs that can satisfy the functional and QoS requirements of an enterprise DRE system. We have therefore developed a system execution modeling tool chain that combines QoS-enabled component middleware and model-driven development (MDD) technologies to create the **Component Workload Emulator (CoWorkEr) Utilization Test Suite (CUTS)**. Software architects, developers, and systems engineers can use CUTS to explore design alternatives from multiple computational and valuation perspectives at multiple lifecycle phases using multiple quality criteria with multiple stakeholders and suppliers. In addition to validating design rules and checking for design conformance, CUTS facilitates “what if” analysis of alternative designs to quantify the costs of certain design choices on end-to-end system performance. For example, CUTS can help determine the maximum number of components a host can handle before performance degrades, the average and worse response time for various workloads, and the ability of alternative system configurations and deployments to meet end-to-end QoS requirements for a particular workload.

In the context of enterprise DRE systems, our CUTS system execution modeling tool helps developers discover, measure, and rectify performance problems early in the system’s lifecycle (e.g., in the architecture and design phases), as opposed to the integration phase, when mistakes are much harder and more costly to fix. This paper shows how we used CUTS to rapidly emulate component-based applications in a representative enterprise DRE system, i.e., shipboard computing, and then perform experiments that systematically estimated and evaluated the end-to-end QoS for key scenarios in this system.

**Paper organization.** The remainder of this paper is organized as follows: Section 2 summaries limitations with prior work on QoS-enabled component middleware and MDD tools in the context of a shipboard computing system case study; Section 3 describes CUTS, shows how it overcomes limitations with prior work, and explains how we resolved key design challenges when developing CUTS; Section 4 shows how we applied CUTS to evaluate the QoS of various deployments in our case study; Section 5 compares our R&D efforts with related work; and Section 6 presents concluding remarks and lessons learned.

2. Background and Case Study

Our work on CUTS has evolved incrementally over the past three years in the context of the DARPA Adaptive and Reflective Middleware Systems (ARMS) program (dtsn.darpa.mil/ixoardarpatech/ixo_FeatureDetail.asp?id=6). ARMS is a multi-phase program that is developing multi-layer resource management (MLRM) services to support product-lines that coordinate a grid of computers to manage many aspects of a ship’s power, navigation, command and control, and tactical operations [15]. The ARMS MLRM services have hundreds of different types and instances of infrastructure components written in ~500,000 lines of Java and C++ code and ~1,000 files developed by six teams at different geographic locations. This section uses our experience on ARMS as a case study to motivate the need for the CUTS system execution modeling tools.

Our initial approach. To address the configuration and deployment problems common to integrating components in enterprise DRE systems, our initial work on ARMS combined QoS-enabled component middleware platforms with MDD tools. QoS-enabled component middleware supports the provisioning of key QoS properties, e.g., (pre)allocating CPU resources, reserving network bandwidth/connections, and monitoring/enforcing the proper use of DRE system resources at runtime, to meet end-to-end requirements. MDD tools combine

- Domain-specific modeling languages (DSMLs), which provide programming notations that formalize the process of specifying application logic and QoS-related requirements using type systems that precisely express key characteristics and constraints associated with DSMLs for particular application domains and

- Model transformations and code generation, which automate and ensure the consistency of software implementations via analysis information associated with functional and QoS requirements captured by models of domain-specific structure and behavior.

In prior work with colleagues at Washington University, St. Louis we developed a QoS-enabled component middleware platform called the **Component-Integrated ACE ORB** (CIAO) [14] that combines Lightweight CCM [4] capabilities (such as standards for specifying, imple-
menting, packaging, assembling, and deploying components) with Real-time CORBA [12] features (such as thread pools and priority preservation policies) to create a Real-time CCM middleware platform. Likewise, we created an MDD tool suite called Component Synthesis using Model Integrated Computing (CoSMIC) [7], which is an integrated set of DSMLs that support the development, deployment, configuration, and evaluation of enterprise DRE systems based on Real-time CCM. CoSMIC is implemented using the Generic Modeling Environment (GME) [9], which is an open-source MDD toolkit for creating and using DSMLs. These tools/platforms are open-source and available from www.dre.vanderbilt.edu.

By combining CIAO and CoSMIC on ARMS, we tackled many integration challenges associated with configuring and deploying enterprise DRE systems by leveraging MDD tools to enforce correct-by-construction design. For example, we used CoSMIC’s model interpreters to generate Real-time CCM XML configuration files [1] and CIAO’s Deployment And Configuration Engine (DAnCE) [5] to deploy the resulting component assemblies on DRE system nodes, as shown in Figure 1.

Figure 1. Integrating CIAO, DAnCE, and CoSMIC

Limitations with our initial approach and common alternatives. To evaluate the benefits of combining CIAO, DAnCE, and CoSMIC, we applied them in phase one of ARMS [16]. Our experience, however, indicated that CIAO, DAnCE, and CoSMIC were insufficient to evaluate the QoS of applications in enterprise DRE systems due to the following limitations:

- **Insufficient performance evaluation.** In the ARMS enterprise DRE system environment, many different applications ran concurrently across networks that included both shared and dedicated components. CIAO, DAnCE, and CoSMIC, however, provided insufficient support for evaluating QoS-related characteristics (such as communication delay, temporal phasing, parallel execution, and synchronization).

- **Serialized phase ordering dependencies.** Application components that exercised the ARMS MLRM infrastructure middleware services were not developed until later in the system lifecycle. The QoS of the infrastructure services therefore was not evaluated adequately under realistic workloads to validate their architecture and design.

We initially considered evaluating enterprise DRE system QoS characteristics in ARMS via simulation. Due to size, interdependencies, and the sheer number of variables involved in ARMS it was impractical to develop and evolve realistic models that simulate complex scenarios. Moreover, while pure simulation can provide valuable information about system QoS behavior, it is hard to leverage simulation results directly in the production operational environment.

3. The Component Workload Emulator (Co-WorkEr) Utilization Test Suite (CUTS)

To overcome the limitations encountered in the ARMS program described in Section 2, we needed more effective technologies to evaluate the end-to-end QoS characteristics of ARMS applications in a production-scale environment, even before any actual application components were developed. Our goals were motivated by our experience in phase one of ARMS and involved:

- **Not obtaining 100% precision, but providing systems engineers and architects with rapid, reasonably accurate estimates of system QoS early in the lifecycle.**

- **Improving the accuracy of our estimates of system QoS incrementally as our understanding of application requirements, implementations, and execution environments increased.**

- **Automatically transitioning select artifacts used in our evaluations (such as models of deployment plans that met end-to-end QoS requirements) to the component-based application and middleware deployments and configurations we were creating.**

To meet our goals and overcome limitations with prior work, we developed the Component Workload Emulator (CoWorkEr) Utilization Test Suite (CUTS). CUTS is a system execution modeling tool chain for creating component-based applications rapidly and performing experiments that systematically evaluate interactions that are hard to simulate. In particular, CUTS provides model-based workload generation, data reduction, and visualization tools to construct experiments rapidly and analyze results from alternate execution architectures. CUTS can also import measured performance data from faux application components running over actual configured and deployed infrastructure middleware services to estimate enterprise DRE system behavior in a realistic environment.

When combined with our prior work on QoS-enabled component middleware and MDD tools, CUTS allowed more robust and complete solutions for emulating actual application components and evaluating QoS earlier in the enterprise DRE system lifecycle. For example, we used CoSMIC to create models of DRE systems composed of faux application components and actual system infrastruc-
ture components. We then used these models with CIAO and DAnCE to deploy all these components based into a representative testbed (www.dre.vanderbilt.edu/ISISlab) and conduct systematic experiments that measured how well the system performed relative to QoS specifications from production computing systems. This remainder of this section presents the CUTS architecture and solutions to design challenges we faced when developing it and applying it to the ARMS case study.

### 3.1 CUTS Architecture

As outlined in Section 2, CUTS is a system execution modeling toolkit designed to (1) emulate portions of enterprise DRE systems (2) collect performance data provided by the emulation, and (3) analyze the data to estimate system QoS and pinpoint potential performance bottlenecks.

At the heart of CUTS is an assembly of CCM components, called a **CoWorkEr** (Figure 2). A CoWorkEr is a faux component that can be programmed rapidly to emulate the expected behavior and resource consumption of its counterpart in the production application.

#### 3.1.1. Workload generation

CoWorkErs can be connected together via their exposed ports to create *operational strings*, which are task graphs that capture the partial ordering of a set of executing software components. Figure 2 shows the key elements of the CoWorkErs, which fall into two broad categories: *workload generation* and *test control and analysis*.

**3.1.1. Workload generation** is implemented in CUTS as an assembly-based CCM component composed of the following monolithic CCM components:

- **The EventHandler** can receive user-defined events. It records the number of events received for each type and performance metrics regarding the delay between original publication and the onset of processing. The EventHandler also tracks the time required to process each event it receives. Workloads, which are performed by the **worker** components described next, may also be associated with receiving combinations and numbers of events.
- **The CPUWorker** performs CPU operations. As with all **workers**, the quantity of work to perform is specified as a number of *repetitions*, which represent an abstract unit of work.
- **The MemoryWorker** performs allocation and deallocation of memory.
- **The DatabaseWorker** performs a series of insert, update, and delete operations on a specified database.
- **The EventProducer** (which is also a worker) publishes events that carry a data payload of the desired size. Events are time-stamped prior to transmission.
- **The Trigger** is provided to represent external input to a simulated application, or regularly scheduled, time-driven processing not resulting from the receipt of an event. **Triggers** provide both periodic and pseudo-random behavior by inducing **workers** to perform a *workload* at a specified interval and probability of occurrence. A **Trigger** can also perform *startup workload* during activation.

To simplify the programming and configuration of CoWorkErs, we created an MDD-based DSL called the *Workload Modeling Language (WML)* [15]. WML is used to characterize the behavior of individual CoWorkErs by specifying their processor, memory, database, and input/output usage profiles. XML characterization files are then generated from a WML model, and subsequently parsed by **EventHandler** and **Trigger** components to dictate the behavior of their respective CoWorkEr.

#### 3.1.2. Test control and analysis

**3.1.2. Test control and analysis** in CUTS includes the following elements:

- **The BenchmarkAgent** completes the CoWorkEr assembly shown in Figure 2. It requests test data collected by **EventHandlers** at a user-defined interval and transmits this data to the **BenchmarkDataCollector**.
- **The BenchmarkDataCollector (BDC)** submits test data to a centralized in-memory **BenchmarkDatabase**.
- **The BenchmarkManagerWeb-interface (BMW)** implements the bulk of the test control and analysis functionality via an ASP.NET application. This manager processes data captured in the **BenchmarkDatabase** and invokes **DAnCE**’s **ExecutionManager** to start and end the deployment of test assemblies. In addition to the web browser interface, the BMW provides a web-services interface that allows any programming language that understands the Simple Object Access Protocol (SOAP) to automate test in CUTS.

![Figure 2. A CoWorkEr Component Assembly](image)

**Figure 2. A CoWorkEr Component Assembly**

To further illustrate the CUTS architecture, Figure 3 shows a complete example setup of CUTS to evaluate QoS in an Enterprise DRE System.

![Figure 3. Example Setup of CUTS to Evaluate QoS in an Enterprise DRE System](image)
Figure 3 shows how CUTS can evaluate the QoS of enterprise DRE systems. Dedicated hosts, called test hosts, run inside the test network and the BenchmarkDataCollector and BenchmarkManagerWeb-interface exist outside the test network. This setup limits outside interference on tests run using CUTS while permitting users to analyze their results either during and after the test run.

3.2 CUTS Design Challenges and Solutions

We now describe key problems encountered when developing and applying CUTS and explain the solutions adopted to resolve these problems.

Challenge 1. Non-intrusive metrics collection. An ad hoc metrics collection system might interfere with the emulation and skew test results. Metric collection should therefore have minimally intrusion and resource usage.

Solution → Decouple metrics collection from emulation, and collect metrics using a 3-phase data acquisition process. TheEventHandler, BenchmarkAgent and BenchmarkDataCollector component, which were described in Section 3.1, work together to collect performance metrics in three separate phases. In phase 1, the EventHandler maintains for each event type a local in-memory record of the number received, the maximum and minimum transmission and processing time, and running totals for transmission and processing time. In phase 2, the BenchmarkAgent obtains the data from the EventHandler at a user-specified interval in a dedicated thread, and resets the EventHandler’s running totals. The BenchmarkAgent transmits the collected data to the BenchmarkDataCollector, which immediately queues the data and returns. In phase 3, the BenchmarkDataCollector dequeues the data and inserts it into a MySQL database. Each phase of the data acquisition process also uses a dedicated thread to minimize the impact of data collection on the emulation.

All data stored and transmitted by the EventHandler and the BenchmarkAgent is a fixed-size to ensure memory usage is bounded by a constant factor. The aspects of metric collection that cause variable memory usage and delays, e.g., queuing and entry of data into a database, are placed the BenchmarkDataCollector, which is deployed on a node not used by a CoWorkEr. Moreover, separate network interfaces can be used to decouple the transmission of metric data from the transmission of CoWorkEr operations.

Challenge 2. Simplify characterization of application workload. Some users of CoWorkErs will be systems engineers or architects, who may not be accomplished at programming with third-generation languages, such as C++ or Java, or configuration languages, such as XML. It is therefore important for CUTS to offer alternatives to programmatic interfaces and dense configuration files for these types of users.

Solution → Provide graphical user interfaces for characterizing, deploying and analyzing applications. CUTS allows users to design simulated applications entirely through visual models. In particular, the CoSMIC and WML DSMLs allow users to create structural and behavioral models of their applications without manually editing configuration files or third-generation language code. Deployment and analysis of the application is provided through an intuitive BenchmarkManagerWeb-interface. More details and examples of WML appear in [15].

Challenge 3. Simplify Customization. CoWorkErs can emulate four categories of core application work (CPU, memory, database, and network resource utilization), but the need for more customized behavior may arise for particular types of enterprise DRE systems. The design of the CoWorkErs therefore needs to support user-defined extensions to its basic work repertoire.

Solution → Support custom CoWorkEr components. In the spirit of CCM, CoWorkErs employ a modular design where any monolithic components comprising the CoWorkEr assembly shown in Figure 2 can be replaced with a customized component that implements the same interface, without requiring modification or recompilation of other components. For example, it is straightforward to replace the default CPUServicer with a FCPServicer that only performs floating-point arithmetic. In addition, GME’s convenient inheritance arithmetic. In addition, GME’s convenient inheritance support makes swapping of components straightforward within a CoSMIC model.

Challenge 4. Descriptive analysis of performance. If a particular emulation shows that a proposed configuration and deployment of enterprise DRE system components will not meet QoS expectations, CUTS users must be able to pinpoint the source of the problem quickly to correct it.

Solution → Present metrics in layers to support general and detailed analysis. In addition to providing a high-level, graphical representation of observed performance vs. deadlines along a critical path, CUTS BenchmarkManagerWeb-interface allows users to view statistics for individual CoWorkErs. A tabular display allows users to view summary statistics for operational strings of CoWorkErs simultaneously, whereas detailed graphs support scrutiny of an individual CoWorkEr’s performance over time. Statistics for processing time can also be subdivided to reflect the four categories of work, thereby allowing analysts to determine whether QoS target requirements are being missed due to reliance upon a sluggish database, paging due to excessive memory allocation, saturation of network bandwidth, etc. Usage and further discussion of these features can be found in Section 4.2.

4. Applying CUTS to Evaluate an Enterprise DRE System

This section describes the design and results of an experiment that uses the CUTS systems execution modeling toolchain to evaluate the QoS of a representative enterprise DRE system from the domain of shipboard computing. This experiment is based upon work conducted in the DARPA ARMS program described in Section 2. The ARMS program provides a representative case study for evaluating CUTS since it runs on general-purpose oper-
The ARMS SLICE Experiment using CUTS

4.1 The ARMS SLICE Experiment using CUTS

4.1.1. Experiment motivation. One of the challenging problems in the second phase of the ARMS program is called the SLICE scenario, which consists of 2 sensors, 2 planners, 1 configuration, 1 error recovery, and 2 effector components. The SLICE scenario requires the transmission of information detected by the sensors to each planner in sequence, then to the configuration component, and lastly to both effectors to perform actions that control devices in the physical world. Components in the SLICE scenario are deployed across 3 computing nodes because the workload generated by each component collectively is more than a single node can handle. The main sensor and effector (represented as sensor-1 and effector-1 in Figure 4 and in following sections) are deployed on separate nodes to reflect the placement of physical equipment in the production shipboard system. Figure 4 shows a model of the end-to-end layout of SLICE components, with the critical path specified by the dashed arrows.

Figure 4. Model of SLICE Showing the Components and Their Interconnections

In phase two of ARMS, the multi-layer resource manager infrastructure was re-implemented to use Real-time CCM (via CIAO and DAnCE), and MDD tools (via CoSMiC), instead of Real-time CORBA and ad hoc deployment mechanisms used in phase one of ARMS. Based on the ARMS phase two development schedule, the integration of components that implemented the SLICE scenario atop the new multi-layer resource management infrastructure was not slated to occur until 12 months into the program to provide sufficient time to finish developing, testing, and optimizing the multi-layer resource management infrastructure. The SLICE scenario, however, uses software components similar to product-lines and challenge problems in phase one of the ARMS program. We therefore already understood each component’s behavior in SLICE, but did not know how overall performance of the SLICE scenario would be affected by the new ARMS multi-layer resource management infrastructure.

In phase one of ARMS, we waited until the integration phase of our schedule to begin benchmarking the system, only to learn none of the QoS requirements were met due to improperly designed multi-layer resource management infrastructure. As a consequence, our schedule slipped and the process of reconfiguring and redeploying ARMS application and middleware components to meet QoS requirements required significant manual effort. To prevent the same problems from happening in phase two of the program, we used CUTS to evaluate the QoS challenges of the SLICE scenario prior to the integration phase. Our goal was to determine which configuration and deployment strategies will enable us to meet the QoS critical path deadline and create a pool of selectable deployment strategies that meet the performance requirements. The underlying hypothesis driving the experiment was much of the performance information could be collected prior to the integration phase by emulating key properties of the SLICE scenario components using CUTS. As a result, less time would be spent integrating and testing the actual SLICE components after they were completed.

4.1.2. Experiment design. For the SLICE scenario, there is a 350 ms QoS critical path deadline, which is representative of the end-to-end execution time of a similar scenario from phase one of the ARMS program. This deadline corresponds to receiving a command event on sensor-1 up to performing an action with effector-1. Sensor-1 and effector-1 must be deployed on separate nodes to meet the constraints discussed in section 4.1.1. Table 1 describes the predicted behavior for two of the SLICE components (which were defined using the Workload Modeling Language) to illustrate the various types of workload and actions for a CoWorkEr.

Table 1. Expected Behavior for 2 SLICE CoWorkErs

The workload specifications for each component listed in Table 1 is based on the behavior of components implemented in phase one of ARMS. We obtained these values by estimating the number and types of operations based our understanding gained by implementing and testing the functionality of the workload generators explained in Sec-
tion 3.1.1. For the predicted behavior for the remaining components, please refer to [13].

Table 2: System Characteristics for Experiment Host

Each host used by ARMS developers in the CUTS-based experiments was an IBM Blade Type L20, dual-CPU 2.8 GHz processor with 1 GB RAM with the characteristics listed in Table 2. The middleware used for the experiment was version 0.4.7 of Ciao/DAncE, and the MDD tools used were version 0.4.6 of CoSMIC, which is the target middleware and MDD tool for the SLICE scenario in ARMS phase 2. Each test was run for 10 minutes.

4.2 Viewing and Interpreting the Results of the SLICE Experiment

This section describes the results of tests that used CUTS to evaluate various deployments of SLICE components onto hosts to (1) test the capability of CUTS, (2) determine which deployment strategies meet the 350 ms critical path deadline when components Sensor-1 and Effector-1 are deployed on separate nodes, and (3) prove that workload generated by SLICE is too much when the critical path components are deployed on a single node. The first listing in Table 3 contains the legend for the CoWorkEr symbols used in the second listing.

4.2.1. Discussion of the hypothesis. Test 4 and 5 were two tests that not only missed the 350 ms deadline, they incurred the worst critical path execution time for all 11 tests. The main purpose of test 4 and 5 was to evaluate our hypothesis that the 350 ms deadline could not be met if all components were deployed on the same node. After completing test 4 and 5, we validated this hypothesis – the workload generated by components in the critical path is more than a single node can handle, so they must be deployed across multiple nodes. On the other hand, test 6 deployed only the components in the critical path on the same node, and had an average execution time of 323 ms. CUTS therefore enabled us to learn that we could meet the 350 ms deadline if only the critical path components were deployed on the same node.

4.2.2. Interpreting the CUTS benchmark data results. Running 11 tests with various deployment strategies provided key information about the current ARMS multi-layer resource management infrastructure. Of the 11 tests, only 3 deployed the critical path components across multiple nodes and completed their end-to-end execution in 350 ms. Of these 3 tests, 2 deployed the critical path across all three nodes and completed it within an average time of 350 ms, and 1 test (test 11) completed it within a worse time of 350 ms. Although we did not exhaust all possible deployment strategies in this experiment, we learned that only 18% (2 out of 11) of the current test passed on their planned infrastructure while meeting the deployment requirements and test 11 yield the best performance.

After running test 1 through 8, only 1 test met the 350 ms end-to-end deadline, and 7 of the tests had faults in their deployment specification, e.g., placing a CoWorkEr on a host with insufficient resources to handle its workload without missing deadlines. We used the CUTS graphical analysis features to help investigate why these deployment strategies did not meet their QoS requirements.

Table 5: Snapshot of the Critical Path Timing Data for Test 8 from the BMW Analysis Page

Tables 4 and 5 show an excerpt of the results provided via the BenchmarkManagerWeb-interface (BMW) for test 8, which measures behavior when the two components in the critical path handling the most workload are deployed
on their own node. Table 4 shows the time to transmit a particular message between two CoWorkErs and how long it took to complete each type of workload – CPU, database, or memory – for Sensor-1. For the CoWorkErs in the critical path in test 8, it took 169.6 ms for Sensor-1 to process its workload after receipt of a command event from Planner-1; 54.03 ms for Planner-1 to perform its workload after receipt of a track event from Sensor-1 or Sensor-2; and 110.66 ms for Planner-2 to perform its workload after receipt of a command event from Planner-1.

For test 8, Sensor-1 and Planner-2 have the longest completion times. As a result of the quantitative analysis provide automatically by CUTS, we realized that the Sensor-1 and Planner-2 CoWorkErs components had a heavier workload than expected, and must be deployed on separate nodes. We then used CoSMIC and DANCE to place the Sensor-1 and Planner-2 CoWorkErs on different hosts, which created the deployment strategies used in test 9, 10 and 11, all of which met the 350 ms deadline. Of those 3 tests, test 11 was the best test case and was the only test to have a worse execution time that meets the 350 ms deadline. In addition, these deployment strategies meet the deployment requirements of placing Sensor-1 and Effector-1 on different nodes, as discussed in Section 4.1.4.

More detailed examples of the types of visualizations and analysis provided by CUTS is presented in [13].

5. Related Work

Distributed system emulation environments. Various environments can be used to emulate and evaluate distributed system behavior. A popular environment is Emulab [6], which provides tools that can be used to configure the topology of experiments, e.g., by modeling the underlying communication links. This topology is then mapped to ~250 physical nodes that can be accessed via the Internet. CUTS enhances the Emulab network-centric focus via the WML and CoSMIC DSMLs that create tests and deployment/configuration specifications at a high-level of abstraction that is more suitable for emulating component-based DRE systems than the NS scripts provided by Emulab to provision communication links.

ModelNet [17] is an environment for evaluating large-scaled distributed systems. In ModelNet, developers emulate multiple clients host using a single host. For example, 100 gnutella clients each with a 1 Mbps bottleneck bandwidth can be emulated on a single dual processor-1 GHz machine. ModelNet also facilitates the emulation of fault and real applications. The CUTS emulation environment is similar to the ModelNet environment in that both address large-scaled distributed systems. CUTS, however, focuses on DRE systems and uses the target architecture to facilitate emulation and performance accuracy. Whereas, ModelNet seeks to provide scalable and accurate solutions using as few hosts as possible.

System execution modeling tools. KLAPER [8] is a modeling language for specifying system behavior for component-based systems. Similar to WML in CUTS, KLAPER allows the specification of workload, such as resource utilization, but it does not specify handling of events. Instead, components are expressed by their provided services and invocations on these services, and not its resources. In contrast, WML allows sequential specification of resource utilization, transmission and receipt of events, and workload types, e.g. event, periodic, or startup.

UPPAAL [3] is a system execution modeling tool that verifies properties of real-time systems. UPPAAL provides a modeling-language and environment for verifying a system’s specified behavior early in the development stage by dynamically validating all possible behaviors with its model-checking simulator. CUTS focuses on other areas, such as (1) the emulation of system behavior on the target systems, (2) benchmarking of a real-time system as a whole and as individual components, and (3) monitoring of flows in the system to verify QoS requirements are met.

RT-UML uses techniques designed to model and evaluate the performance of component-based systems [11]. These performance engineering techniques use RT-UML to define services and QoS policies for components, though modeling system behavior is future work. This technique is designed to be supported by external simulation tools, which are still under development. WML enhances this effort by providing a working DSML tool that allows developers to specify a component-based system behavior, which is emulated by CUTS.

Evaluation techniques for component architectures. [20] discusses a technique called trace-based analysis for Enterprise Java Bean (EJB) components. In trace-based analysis, different execution traces in a component are monitored and dumped to a trace file contained on the host. After the emulation, the trace files are parsed and combined with the deployment descriptors, which define the structure of the system, to determine the different paths of execution in the system. CUTS is similar to trace-based analysis since it collects traces of execution times, but these traces are logged to a central database. CUTS also monitors a predetermined execution paths, whereas [20] uses methods to reconstruct every path autonomously, as it does not monitor performance in real-time over the duration of the emulation. [20] also focuses on service calls, or facet operations, whereas CUTS performance metrics are events sent between components.

[18] and [19] discuss vertical profiling evaluation techniques in the context of EJB. In vertical profiling, performance metrics based on the types of operations and actions (e.g., cache misses and CPU cycles) are collected in trace files across multiple executions of the same tests. The trace files are then fused through a process called trace-alignment using a common metrics that occurs in the source traces. After the traces are aligned, correlation analysis is applied to the traces to help determine what other metrics collected in the trace may influence its behavior. [19] also discusses how to automate this process.
CUTS provides a similar approach in the context of CCM that allows analysis of individual actions and operations in a component. CUTS, however, goes further to allow the analysis to happen at real-time with the emulation.

**Architectures for deployment and configuration of components.** Proactive [2] is a framework for component deployment and configuration designed for conventional Java applications running on JVMs. In contrast, CUTS leverages DAnCE [5], which is targeted for deploying and configuration components in DRE systems.

The Globus Toolkit [10], which is part of the Open Grid Standard Architecture (OGSA), is another framework that handles deployment and configuration of components for Grid computing. Unlike DAnCE, however, Globus does not provide DSMs for modeling various concerns of enterprise DRE systems and validating systems before deploying them. Lastly, the DAnCE framework conforms to the OMG D&C standards, which allows it to leverage other R&D efforts based on the OMG D&C specifications, such as OpenCCM and MICO-CCM.

### 6. Concluding Remarks

This paper described the **Component Workload Emulator (CoWorkEr) Utilization Test Suite (CUTS)**. CUTS is a system execution modeling toolchain that simplifies the creation of – and experiment with – simulations of applications that help evaluate the QoS of component-based enterprise DRE systems. We also described the design and implementation of CUTS, along with the challenges we encountered and solutions we applied.

Our experience applying CUTS to the SLICE scenario in phase two of the ARMS program showed how systems execution modeling tools can decrease the time spent resolving integration problems. Instead of waiting until full system integration, CUTS allowed us to test deployments of the ARMS multi-layer resource management infrastructure in the actual target environment using emulated application components. When combined with other QoS-enabled component middleware and MDD tools, alternative deployment plans could be evaluated rapidly earlier in the lifecycle, thereby reducing the time and effort spent in integration. Although phase two of the ARMS program is still ongoing, CUTS has already saved significant amounts of time and effort compared to phase one.

The following summarizes the benefits of applying CUTS based on our experience thus far:

- **CUTS** allowed us to emulate system components using the target hardware and software infrastructure, instead of waiting until completely implementing the real components and trying to resolve all issues during integration phase, as we had attempted to do (rather unsuccessfully) in ARMS phase 1.
- **CUTS** allowed us to rapidly create and quantitatively evaluate a range of deployment plans to see how they impacted end-to-end QoS behavior. Much more time and effort would have been required if these tests were conducted manually, i.e., without the visual MDD functionality and automation provided by CUTS and the underlying CoSMIC MDD tools and CIAO/DAnCE middleware.
- **CUTS** provided qualitative performance analysis to assist in locating deficiencies in current deployments so we can determine alternative deployments that meet end-to-end QoS requirements more effectively.
- The use of MDD tools enabled CUTS to substitute real components for the emulated ones quickly, so we can incrementally evaluate QoS performance with more realistic workloads as knowledge of the application and system infrastructure evolves.

Although our use of CUTS in ARMS phase two was promising, we also discovered that the following work is needed to improve the evaluation of QoS in component-based enterprise DRE systems:

- There were test cases in the empirical results in Section 4.2 where the critical path deadline was missed significantly. After further analyzing these results, specifically after test 8, we realized that messages not on the critical path were handled at the same priority as arbitrary messages in the system. We therefore need to extend CUTS to allow QoS specifications for the various components of a CoWorkEr.
- CoWorkErs currently generate a pre-defined set of events, which is representative of a certain class of statically provisioned DRE systems. Enterprise DRE systems, however, often must adapt to changes in the environment. We therefore need to extend CUTS and WML to permit specification and enforcement of adaptive behavior for QoS evaluation.
- **CUTS** uses XML specifications to configure the behavior of generic CoWorkErs, whose internals and - interfaces do not resemble the components they emulate. We are therefore extending WML to generate proxy CoWorkErs that simplify the interchange of - simulated application components. This enhancement will also enable the collection of performance metrics from actual and emulated components to evaluate their similarities and differences.
- Enterprise DRE systems can share resources either locally or remotely, which affects QoS performance of the system. Further work is therefore needed to extend CUTS to allow CoWorkErs to share resources both remotely and locally for QoS performance evaluation.
- QoS does not always depend on behavior at the application level. In many instances, QoS can depend on performance metrics at the different layers of middleware below the application, and the machine, e.g., CPU operations and cache misses. CUTS therefore needs to be extended to monitor performance metrics at all levels in an application and apply QoS requirements to these metrics.
• Derivation of workloads used in the SLICE scenario required us to estimate each component’s workload based on our understanding of performance characteristics of similar component from ARMS phase one. This process is labor intensive and faulty if the characteristics are misinterpreted. Since we currently rely on “trial and error” methods we are developing heuristics that will help us derive workloads given performance characteristics and allow us to automatically derive workloads using the workload heuristics and performance characteristics.

CUTS is currently being transitioned from the DARPA AMRS program to a production shipbuilding program to assist system engineers and architects in evaluating QoS performance metrics of DRE systems. Our future R&D efforts will therefore focus on adding the capabilities listed above to further enhance CUTS and provide system architects and engineers with a stronger tool suite.
